Blood

Blood is a life-sustaining fluid that circulates through the heart and blood vessels. It carries oxygen and nutrients to the tissues and waste products to the lungs, liver and kidneys, where they can be removed from the body. Usually when blood is removed from the body it forms a solid blood clot. However, if clotting is prevented by mixing with an anticoagulant, the blood separates, under the influence of gravity, into three layers (Fig. 1.1). The bottom layer is deep red in colour and is composed of red cells. The top layer is clear and pale yellow. It is called plasma and is composed of various salts and proteins dissolved in water. In between is a narrow layer called the buffy coat because of its buff or yellowish white colour. The buffy coat is composed mainly of cells of a variety of types, collectively known as white cells. In addition there are small cellular fragments, called platelets, which have a role in blood clotting.

The blood film

Although we can judge the proportions of red cells and white cells in a tube of sedimented blood, we get far more information if the blood is carefully mixed and a thin layer is spread on a glass
slide to form a blood film. The blood cells are then preserved by exposure to the alcohol methanol, a process known as fixation. The fixed film of blood is stained with a mixture of several dyes so that the individual cells can be recognized when they are examined with a microscope. After staining, the colour of red cells is enhanced and the white cells and platelets, which would otherwise be transparent and colourless, have acquired a variety of colours that allow their detailed structure to be recognized. One of the commonest mixtures of dyes used to stain blood cells is the May–Grünwald–Giemsa (MGG) stain, named after its inventors. All the photographs in this book are of MGG-stained blood films.

**Red cells**

The most numerous cells in a blood film are the red cells, also known as erythrocytes. Normal red cells are disc-shaped but are thinner in the centre (Fig. 1.2). As a consequence, on a stained blood film, they have a circular outline and a paler central area (Fig. 1.3). Red cells owe their pinkish-brown colour to the presence of a complex protein, haemoglobin, which is their major constituent. Enhancement of their colour in a stained film is
because haemoglobin takes up eosin, one of the dyes of the MGG stain. In the body it is haemoglobin of the red cells that, in the lungs, combines with oxygen from inspired air and transports it to tissues where it is needed for the metabolic processes supplying the energy needs of the body. Mature red cells in humans (although not in some other species) differ from most body cells in that they do not have a nucleus. Red cells are produced in the bone marrow and usually lose their nuclei when they are released into the blood stream.
White cells

In healthy people there are at least five types of white cell, or leucocyte, in the circulating blood. Unlike red cells, white cells have retained their nuclei. The cell is therefore made up of a nucleus and cytoplasm. The cytoplasm is the site of protein synthesis and other cellular functions. The nucleus is composed of chromatin, which is mainly deoxyribonucleic acid (DNA), carrying genetic messages. Genetic messages are transmitted from the nucleus to the cytoplasm by ribonucleic acid (RNA).

White cells are divided into granulocytes (also known as polymorphonuclear leucocytes) and mononuclear cells. There are three types of granulocyte and two types of mononuclear cell (Fig. 1.4). The names are not very logical but they have been in use for a long time and are generally accepted. Granulocytes are so named because their cytoplasm contains prominent granules. However, monocytes also have granules and so do some lymphocytes. The term ‘granulocyte’ should not be used as a synonym for neutrophil. The term polymorphonuclear leucocyte refers to the very variable nuclear shape that is typical of granulocytes. The term mononuclear cell means that the cell has only a single nucleus. However, this is true of granulocytes, as well as of the cells conventionally referred to as mononuclear. The functions of the various leucocytes are summarized in Table 1.1.

Neutrophils

Neutrophils (Fig. 1.5) have a nucleus that stains purple and is divided into two to five segments or lobes. The lobes are separated by a thin strand or filament of nuclear material. The nuclear chromatin is heterogeneous with some clumping. The cytoplasm of neutrophils is very pale pink and is packed with fine lilac-staining granules. The visible granules are actually the primary or azurophilic granules, the secondary or specific granules being invisible by light microscopy but conveying the pink tinge to the cytoplasm. The term ‘neutrophilic’ indicates that at this stage of maturation the primary granules owe their colour to uptake of both the acidic and the basic components of the stain.
In females a proportion of the neutrophils have a very small lobe, known as a ‘drumstick’, protruding from the nucleus (Fig. 1.6). It represents the inactive X-chromosome of the cell.

Neutrophils are produced in the bone marrow. They spend 6–10 hours in the blood stream before moving from capillaries into tissues, where they have a life-span of 1–2 days. The major function of neutrophils is as tissue phagocytes. They move preferentially to sites of infection or inflammation where they ingest, kill and break down bacteria. The process of moving to sites of
### Table 1.1 The functions of leucocytes.

**Fig. 1.5** A normal neutrophil with a bilobed nucleus and cytoplasm containing delicate lilac-staining granules. The other nucleated cell is a small lymphocyte.
infection or inflammation, in response to activated complement components and chemical signals released by a variety of cells, is known as chemotaxis. The process of ingesting bacteria is known as phagocytosis.

**Eosinophils**

Eosinophils (Fig. 1.7) have a nucleus that is usually bilobed and pale blue cytoplasm, which is packed with large refractile, orange-red granules. The granules are referred to as eosinophilic because they take up the acidic dye eosin. Eosinophils are produced in the bone marrow and circulate in the blood stream.
for up to a day before migrating to tissues, where they survive 8–12 days. They respond to chemotactic stimuli, are phagocytic and can kill ingested organisms. They are important in the body’s defences against tissue parasites, being able to discharge their granule contents extracellularly, seriously damaging large parasites. Eosinophils are also involved in allergic reactions.

**Basophils**

Basophils (Fig. 1.8) have a lobulated nucleus, which is often obscured by the large purple-staining granules that pack the very pale blue cytoplasm. The secondary granules are referred to as basophilic because they take up basic components of the stain (such as methylene blue). In fact they stain metachromatically with basic stains, that is, the granules react with a blue dye to produce a purple colour. Basophils are produced in the bone marrow and circulate in the blood in small numbers, for many days, before migrating to tissues. They have a role in defence against helminth infections and in allergic and inflammatory responses.

**Lymphocytes**

Lymphocytes are the second most numerous circulating white cell after neutrophils. They are smaller than granulocytes, with a round or somewhat irregular outline and pale blue, clear cytoplasm.
Some lymphocytes have a variable number of azurophilic (pinkish-purple) granules. Lymphocytes are divided into three morphological categories, depending on their size, the amount of cytoplasm and the presence or absence of cytoplasmic granules. These categories are small lymphocyte (Fig. 1.5), large lymphocyte (Fig. 1.9) and large granular lymphocyte (Fig. 1.10). Small lymphocytes are most numerous. The nuclear chromatin of lymphocytes may be dense and homogeneous (particularly in small lymphocytes) or more lightly staining and somewhat heterogeneous (particularly in large lymphocytes).

**Fig. 1.9** A large lymphocyte with a less densely staining nucleus than occurs in a small lymphocyte and more plentiful pale blue cytoplasm. A nucleolus is apparent, top left in the nucleus.

**Fig. 1.10** A large granular lymphocyte showing a moderate number of prominent azurophilic granules in clear cytoplasm.
Occasional normal lymphocytes show a discrete but ill-defined paler structure within the nucleus, which is the nucleolus.

Lymphocytes are produced from lymphoid stem cells in the bone marrow and probably the thymus. Their function is in tissues such as lymph nodes, spleen, tonsils and the lymphoid tissue associated with mucous membranes. They circulate in the blood stream, enter lymphoid tissues and emerge again from lymphoid tissues into lymphatic channels, where they form one constituent of a clear fluid known as lymph. Lymphatics drain into the thoracic duct and ultimately into the blood stream. This process of continuing movement between tissues and the blood stream is known as lymphocyte recirculation. Lymphocytes function in the body’s immune responses, both innate and adaptive to antigenic stimuli. They are divided into three functional types: B cells, T cells and natural killer (NK) cells. B cells differentiate in tissues into plasma cells, which secrete antibodies, thereby providing humoral immunity. T cells function in cell-mediated immunity as do NK cells. T cells also modulate B cell function, having both helper and suppressor functions. The functional categories of lymphocyte show little correlation with morphological categories except that large granular lymphocytes are either T cells or NK cells. However, other T cells cannot be distinguished morphologically from B cells. The functional categories of lymphocytes are of far more importance than the morphological categories.

**Monocytes**

Monocytes (Fig. 1.11) are the largest normal blood cell. They have lobulated nuclei and voluminous cytoplasm that is greyish-blue, is sometimes opaque and may be vacuolated or contain fine azurophilic granules.

Monocytes have an intravascular life-span of several days. They function mainly in tissues where they differentiate into long-lived macrophages (sometimes called histiocytes). Monocytes and macrophages respond to chemotactic stimuli and are phagocytic. They are part of the body’s defences against bacterial and fungal infections and also ingest and break down dead and dying body cells. They present antigen to lymphocytes.
Monocytes secrete chemical messengers, known as cytokines, which influence the behaviour of other body cells, including blood cells and their precursors. Monocytes differentiate not only into macrophages but also into various specialized cells, specific to different organs, such as the Kupffer cells of the liver, the microglial cells of the brain and the osteoclasts of bone.

**Platelets**

Platelets are produced within the vascular channels (sinusoids) of the bone marrow by the fragmentation of the protruding cytoplasm of large bone marrow cells known as megakaryocytes. They are thus not, strictly speaking, cells but rather are fragments of the cytoplasm of cells.

Platelets are considerably smaller than red cells and white cells [Fig. 1.11]. They are pale blue with fine azurophilic granules, which tend to be clustered in the centre of the platelet. When blood films are made, as is generally the case, from anticoagulated blood, the platelets are usually discrete and separate from each other, but in some circumstances they form clumps or aggregates.
Peripheral blood cells are produced in the bone marrow. Their precursors are referred to as haemopoietic cells (Fig. 1.12). The only significant function of haemopoietic cells is the production of mature end cells. Recognizable haemopoietic precursors are present in the circulating blood of healthy subjects but, except in the neonatal period and during pregnancy, they are quite uncommon and are not often noted in a blood film. They are much commoner in patients with leukaemia or other haematological disorders and in patients with severe infection or other serious systemic diseases.

**Haemopoietic cells**

Peripheral blood cells are produced in the bone marrow. Their precursors are referred to as haemopoietic cells (Fig. 1.12). The only significant function of haemopoietic cells is the production of mature end cells. Recognizable haemopoietic precursors are present in the circulating blood of healthy subjects but, except in the neonatal period and during pregnancy, they are quite uncommon and are not often noted in a blood film. They are much commoner in patients with leukaemia or other haematological disorders and in patients with severe infection or other serious systemic diseases.

**Myeloblasts**

Myeloblasts (Fig. 1.13) are very rare in the blood of healthy subjects. They are larger than lymphocytes but often smaller than monocytes. They have a high nucleocytoplasmic ratio and scanty
to moderate amounts of cytoplasm, which varies from weakly to moderately basophilic. (Basophilic in this context indicates a blue colour consequent on the uptake of basic dyes.) The nucleus is approximately round, nuclear chromatin is diffuse and nucleoli may be apparent. In patients with leukaemia and related disorders, the cytoplasm may contain small numbers of azurophilic granules or other inclusions or vacuoles (see page 90). Myeloblasts are precursors of neutrophils, eosinophils and basophils.

**Promyelocytes**

Promyelocytes (Fig. 1.14) are rare in the blood of healthy people. They are larger than myeloblasts with more plentiful cytoplasm and consequently a lower nucleocytoplasmic ratio. The cytoplasm is more basophilic than that of a myeloblast and contains azurophilic (pinkish-purple) primary granules. Sometimes there is a more lightly staining zone in the cytoplasm adjacent to the nucleus, which represents the Golgi apparatus, where granules are produced. The nucleus is round or oval, is usually eccentric, shows some chromatin condensation and has a visible nucleolus.

Because they have no specific (lineage-associated) granules, the promyelocytes that are precursors of neutrophils, eosinophils or basophils cannot generally be distinguished from each other.
Myelocytes

Myelocytes [Fig. 1.15] are uncommon in the blood of healthy subjects except in the neonatal period and during pregnancy. They are smaller than promyelocytes. They have not only azurophilic or primary granules but also secondary granules characteristic of specific lineages, namely neutrophilic, eosinophilic or basophilic granules. The myelocyte nucleus is round or oval and shows chromatin condensation; no nucleolus is apparent.
Small numbers of neutrophil metamyelocytes (Fig. 1.16) are present in the blood of healthy subjects. Basophil and eosinophil metamyelocytes are not seen in the blood of healthy subjects. Metamyelocytes have similar characteristics to myelocytes but differ in that the nucleus is indented, U-shaped or C-shaped and the granules have altered their staining characteristics.

**Band cells**

Neutrophil band forms (Fig. 1.17) are present as a minor population in the blood of healthy people. They are intermediate in characteristics between metamyelocytes and mature neutrophils. The nucleus has an irregular shape with some parallel edges so that it resembles a band or ribbon. It differs from a mature or segmented neutrophil in that the nucleus is not divided into distinct lobes or segments. Eosinophil and basophil band forms are quite uncommon.

**Nucleated red blood cells**

Nucleated red blood cells (NRBCs), or erythroblasts (Fig. 1.18), are present in very small numbers in healthy people, except during the neonatal period. Those most likely to be released
into the blood stream are late erythroblasts. They can be readily recognized because the cytoplasm is at least partly haemoglobinized giving them a pinkish or lilac tinge. NRBCs have a superficial resemblance to lymphocytes but can be distinguished from them not only by the colour of the cytoplasm but also by the lower nucleocytoplasmic ratio.

**Fig. 1.17** A neutrophil band form (left) compared with a segmented neutrophil (right).

**Fig. 1.18** A nucleated red blood cell (NRBC) in a patient with haemolytic anaemia showing a small round nucleus with condensed chromatin and cytoplasm that is bluish-pink because of the presence of both ribosomes, responsible for the blue tinge, and haemoglobin, responsible for the pink tinge.
The blood count

Haematology laboratories not only examine blood films. They also perform various measurements relating to the haemoglobin content of the blood, the characteristics of red cells, and the number of red cells, white cells and platelets. These measurements are collectively referred to as a blood count or full blood count (FBC). During illness, abnormalities can develop in any of the cells in the blood. The purpose of performing a blood count and examining a blood film is to detect quantitative and qualitative abnormalities in blood cells. Their detection often helps in diagnosis and in the treatment of the patient.

Haemoglobin concentration

If red cells are lysed, the haemoglobin is released from the red cells and forms a solution in the plasma. The haemoglobin concentration (Hb) can be measured biochemically by light absorption at a specified wavelength after a chemical reaction that converts haemoglobin to cyanmethaemoglobin or to lauryl sulphate haemoglobin. Hb is measured in grams per litre (g/l). A fall in the Hb is referred to as anaemia.

Haematocrit or packed cell volume

An alternative way of detecting anaemia is to centrifuge a tube containing an aliquot of blood and measure the proportion of the column of blood that is occupied by the red cells (the packed cell volume, or PCV). Nowadays an equivalent measurement is made by various automated instruments using a quite different principle to get the same information. This test is called a haematocrit (Hct). This measurement is expressed as a decimal percentage, that is, as litres/litre (e.g. 0.45).

Cell counts

Traditionally blood cells were counted by diluting a small quantity of blood in a diluent, which could also stain the cells or, if white cells or platelets were to be counted, could lyse the more
numerous red cells. The diluted blood was placed in a counting chamber of known volume and the number of cells present was counted microscopically. Such a method of counting blood cells is very labour-intensive and not suited to the large number of blood counts needed in modern medical practice. Nowadays blood cells are counted by large automated instruments. A stream of cells in a diluent passes through a sensing zone. They are sensed either because they pass through an electric field or because they pass through a beam of light. Each cell passing through the sensing zone generates an electrical impulse, which can then be counted. Red cells are both relatively large and relatively numerous and so can be readily counted. White cells can be counted by lysing the more numerous red cells or by altering the red cells in some way so that they are ‘invisible’ to the instrument. Platelets are distinguished from red and white cells by their smaller size. Cell counts are expressed as the number of cells in a litre of blood. The red blood cell count (RBC) is expressed as a number×10^{12} per litre (e.g. 5×10^{12}/l). The white blood cell count (WBC) and platelet count are expressed as a number×10^9 per litre (e.g. 7.5×10^9/l and 140×10^9/l). A white cell count of 7.5×10^9/l means that there are 7,500,000,000 cells in a litre of blood.

**Red cell indices**

Red cells can vary in their size and in the amount of haemoglobin contained in an individual cell. Abnormalities in both these cell characteristics are common in certain inherited abnormalities and when people are sick. Diagnostically useful information can be obtained by measuring them. Traditionally the size of red cells was estimated by dividing the PCV by the number of cells in the blood to give a mean cell volume (MCV). The haemoglobin content of individual cells was estimated by dividing the Hb by the RBC to give a mean cell haemoglobin (MCH). The concentration of haemoglobin in individual cells was estimated by dividing the Hb by the PCV to give a mean cell haemoglobin concentration (MCHC). Nowadays, not only has the PCV been replaced by the automated Hct but the size of a red cell is calculated from the height of the electrical impulse that is generated when the cell
passes through a light beam or through an electrical field. As the automated instruments also measure the Hb, it is a simple matter for the red cell indices to be produced automatically as part of the blood count. Instruments can be designed to measure the MCV and calculate the Hct from the MCV and the RBC or, alternatively, to measure the Hct and calculate the MCV from the Hct and the RBC. The formulae that relate the various red cell indices to each other are as follows:

\[
MCV = \frac{Hct (l/l) \times 1000}{RBC (cells/l) \times 10^{-12}} \quad (1)
\]

For example, if the Hct is 0.33 and the RBC is \(4.1 \times 10^{12}/l\), then

\[
MCV = \frac{0.33 \times 1000}{4.1} = 80.5 \text{fl (femtolitres)}
\]

(In understanding this formula and the following ones, it should be noted that if the RBC is \(4.1 \times 10^{12}/l\) then 4.1 is the RBC/l \(\times 10^{-12}\).)

\[
MCH = \frac{Hb (g/l)}{RBC (cells/l) \times 10^{-12}} \quad (2)
\]

For example, if the Hb is 123 g/l and the RBC is \(4.1 \times 10^{12}/l\), then

\[
MCH = \frac{123}{4.1} = 30 \text{pg (picograms)}
\]

\[
MCHC = \frac{Hb (g/l)}{Hct (l/l)} \quad (3)
\]

For example, if the Hb is 123 g/l and the Hct is 0.33, then

\[
MCHC = \frac{123}{0.33} = 373 \text{ g/l}
\]
If an instrument measures the RBC rather than the Hct, then the formula is

$$\frac{\text{RBC}}{1 \times 10^{-12}} = \frac{\text{Hct} (1/\text{l}) \times 1000}{\text{MCV} (\text{fl})}$$

(4)

For example, using the same values as above:

$$\frac{\text{RBC}}{1 \times 10^{-12}} = \frac{0.33 \times 1000}{80.5} = 4.1$$

**Normal ranges**

In order to interpret blood counts it is necessary to know what is normal. This is usually done by reference to either a normal range or a reference range. A reference range is more strictly defined than a normal range but both represent the range of test results that would be expected in healthy people of the same age and sex (and, if relevant, of the same ethnic origin) as the person being investigated. Conventionally, both types of range are expressed as the central 95% of test results that would be expected in healthy people. The reason for excluding the top 2.5% and the bottom 2.5% is that there is usually an overlap between test results of healthy people and of those who are sick. A 95% range has been chosen to avoid either classifying too many healthy subjects as abnormal or missing relevant abnormalities in patients who are sick. It is clear that for any one test 5% of healthy subjects will have results falling outside the ‘normal’ range. Conversely, a patient who is sick may have a test result that is abnormal for him or her but that is still within the normal range. For example, a man may have a large gastrointestinal haemorrhage, causing his Hb to fall from its normal level of around 160 g/l to 140 g/l. The latter value, 140 g/l, is within the range expected for a healthy adult man but for this particular patient it is abnormal. This is because the range of test results expected in a group of healthy people is much wider than the range expected if the same test is repeated day after day in the same person. Usually we have no way of knowing what is
‘normal’ for a particular individual and so we have to resort to comparing his or her test results with a normal range.

The statistical distribution of test results differs for different tests. Many tests, for example the Hb, show a normal or Gaussian distribution. This means that if the distribution of the test results is plotted on graph paper a bell-shaped curve is obtained (Fig. 1.19a). If this is so, the 95% range can be calculated by estimating the mean ± 2 standard deviations. Other test results, for example the WBC (Fig. 1.19b), have a skewed distribution that only becomes bell-shaped if the test results are plotted on logarithmic graph paper. Test results with this type of distribution require special statistical treatment to derive the normal range.

Some normal ranges applicable to healthy people are shown in Tables 1.2–1.4. However, it should be noted that the test results for some haematological variables, for example the MCV, vary according to the method of measurement, and it is desirable for laboratories to derive their own normal ranges for their own automated instruments by obtaining blood samples from a large number of healthy people. In the case of children, it is always difficult to obtain blood samples from large numbers of healthy individuals of various ages. As a consequence, published normal ranges for children are not as reliable as those for adults.
How to examine a blood film

Blood films should be examined in a systematic way. First the film should be examined without using the microscope, to make sure it is well spread (not too thick, too long or too short) and that its staining characteristics are normal. A film that is a deeper blue than other films stained in the same batch is usually indicative of an increase in the concentration of plasma proteins. This can be diagnostically important since it is often caused by multiple myeloma (a plasma cell malignancy) (see page 85) or by chronic inflammatory disease.

RDW, red cell distribution width; HDW, haemoglobin distribution width.
The differential white cell counts and the platelet counts are for Technicon H.1 series automated instruments. The ranges are wider for manual differential counts, particularly for monocytes, eosinophils and basophils. Platelet counts are very dependent on the method used for counting and should be assessed only in relation to a normal range derived for the instrument or method in use.

Note that if the WBC is $3.7 \times 10^9$/l then 3.7 is the WBC $\times 10^{-9}$/l.

It should be noted that the lower RBC, Hb, Hct and MCV values observed in Afro-Caribbean and African people are likely to be consequent on a high prevalence of thalassaemia trait and haemoglobinopathies rather than on other ethnic differences. It is therefore appropriate to use Caucasian reference ranges for red cell variables for Afro-Caribbean and African people.

* Ranges will be wider for manual differential counts than for automated counts.

† The lymphocyte count is up to $8 \times 10^{9}$/l in 2-year-olds, up to $5.5 \times 10^{9}$/l in 3- and 4-year-olds, and up to $4.5 \times 10^{9}$/l in 5-year-olds.
Next the film is examined microscopically at low power (e.g. with a ×25 objective) so that a large part of the film can be scanned rapidly to detect any abnormal cells present in small numbers. Finally the film is examined at a higher power (e.g. with a ×40 or ×50 objective) so that the detailed structure of cells can be assessed. The great majority of films can be evaluated perfectly adequately without using high power (i.e. a ×100 oil immersion objective). High power can be reserved for making a detailed assessment of films that show significant abnormalities requiring further assessment. In examining a film be sure to look specifically at red cells, white cells and platelets so that no abnormality is inadvertently overlooked. Be sure to look at the edges and tail of the film where abnormal cells and platelet clumps may be found.

Finally, decide if a differential count is needed. Nowadays this will often have been performed by an automated instrument but you may need to verify its accuracy, and in leukaemia you may need to carry out a manual differential count, that is one performed with the aid of a microscope.

Learning to look at blood films

When learning to recognize cells for the first time it is useful to compare cells seen down the microscope with photographs. Examining films on a double-headed microscope with an experienced laboratory worker is also very valuable. To learn to recognize high and low WBCs and platelet counts, start by comparing the film appearance with the count on an automated instrument. After you have had some experience try to estimate what the count will be before you look at the test results. Later you will need to be able to do this fairly accurately so that you can recognize erroneous instrument counts. Similarly, start by looking at films with high and low MCVs and compare the size of the red cells with neutrophils and lymphocytes until you can recognize large and small red cells. When you have had some experience, try to estimate the approximate MCV before you look at the test results. Eventually you will be able to judge the MCV, at least to within 5–10 fl.
Recognizing problems with the blood sample

Before carrying out a detailed assessment of a blood film it is important to detect any abnormal characteristics of the specimen that might interfere with your assessment of the film or with the accuracy of the automated count. The most common problem is storage artefact [Fig. 1.20]. This occurs when blood has been at room temperature for a day or more before reaching the laboratory. The red cells turn into echinocytes, that is their shape alters so that the surface is covered with numerous short, regular projections. This process is also known as crenation. Some of the white cells develop fuzzy outlines or disintegrate entirely when the blood film is spread. The nuclei of neutrophils become dense, homogeneous and round and may break up into two or more round masses. It is important not to confuse these degenerating neutrophils with NRBCs. They have a lower nucleocytoplasmic ratio and the cytoplasm is pink and slightly

Fig. 1.20 Storage artefact. The red cells are crenated and one neutrophil (top left) has a nucleus that has become round, dense and homogeneous. A second neutrophil has retained its form but a third leucocyte (right) has a fuzzy outline and has disintegrated to the extent that its lineage cannot be recognized with certainty. [Compare the degenerating neutrophil, top left, with the nucleated red cell shown in Fig. 1.18.]
granular rather than reddish-brown. It is impossible to give any reliable opinion of films showing storage artefact. If the blood count is normal they can usually be ignored but if there is any reason to suspect a haematological abnormality a fresh blood sample must be obtained.

A common cause of inaccurate blood counts is partial clotting of the specimen or aggregation of the platelets. Platelets may aggregate because they have been activated (i.e. the process of blood clotting has started) or because there is an antibody present in the plasma that leads to platelet aggregation in blood that is anticoagulated with ethylenediaminetetra-acetic acid (EDTA). Aggregated platelets form masses between the red cells, which may contain intact platelets (Fig. 1.21) or may be composed of totally degranulated platelets, which stain pale blue. Less often, partially clotted samples contain fibrin strands, which are seen as pale blue or almost non-staining linear structures running between and deforming red cells (Fig. 1.22). Another in vitro artefact, less common than platelet aggregation but one that can also lead to falsely low platelet counts, is platelet satellitism (Fig. 1.23).

Less common artefacts that should be recognized are those due to accidental freezing or overheating of the blood specimen before it reaches the laboratory and the presence of lipid (fat) in the plasma. All these abnormalities cause anomalous blood counts.

When assessing blood films, always note the age, sex and ethnic origin of the patient and keep in mind what would be normal for that individual. Also consider the clinical details so that you can look carefully for any specific abnormalities that might be relevant, keeping in mind that the clinical details may provide you with an obvious explanation for an abnormality you have noted. For example, if the clinical details were ‘alcohol excess’ you would not be surprised to find that the patient had macrocytosis.

and you would go on to see if there were stomatocytes or any of the other abnormalities that can be caused by alcohol. Your report of these abnormalities would give the clinician very specific information that would help to confirm his/her clinical suspicion. Interpret the blood film also in the light of the automated count, seeking to explain further any abnormality that has been indicated.
